ABSTRACT

Río Tinto provides ideal conditions for studying the role of colloidal particles in concentrating elements that could have environmental impacts like U and Th, and their influence on the transport of these radionuclides to Ría de Huelva estuary (Spain). To achieve this objective, ultrafiltration experiments were developed on the Río Tinto waters samples, in order to separate colloids by different sizes (50 kDa, 10 kDa, 5 kDa, 3 kDa). Samples obtained from the ultrafiltration performed with 50 kDa and 3 kDa were analysed to find out concentration using appropriate techniques (ICP-MS) and radionuclides activities have been determined for each of them. An ultrafiltration permeation model describes the relationship between log of concentration of the investigated element in the permeate solution plotted versus log of concentration factor (CF), which is the ratio of initial volume divided by the retentate volume. If there is a constant permeation, this relationship should result in a linear pattern and it can be used to predict the ultrafiltration behaviour of U and Th in this peculiar waters from Río Tinto acid mine drainage system. Experiments were carried out using concentration factor from 1,07 to 1,73, with the aim to investigate if a permeation model, already proved for higher concentration factor, could be applied for lower values too. The behaviour of U can be predicted by a permeation model that provides a permeation coefficient (P_c) of 0,813 for $U < 50$ kDa and $P_c = 0,626$ for $U < 3$ kDa. The permeation model can just show that little retention for U occurs and that the permeation behaviour of U can be considered the same even at low concentration factors. The application of the permeation model on Th 50 kDa samples failed because the membrane was not retaining in quantitative form, but it could be possible derived a $P_c = 0,360$ for Th from the 3 kDa experiments, result that, anyway, could be due to artefactual retentions. Using low concentration factors, the colloidal concentration cannot be estimated by the permeation model for both U and Th. Concentration of U amounts to values from 4,73 $\mu\text{g/L}$ to 6,54 $\mu\text{g/L}$, while the range for Th is from 13,0 $\mu\text{g/L}$ to 28,0 $\mu\text{g/L}$, but no significant differences among the permeate and the retentate were found. Both the elements are present in higher concentrations respect to their content in common natural waters, according to the predict character of the investigated elements in so acidic conditions, in which both can stay in dissolved form and even colloids and all of solid phases will be disintegrated. $^{234}\text{U}/^{238}\text{U}$ activity ratios range between 1,761 and 2,060. The disequilibrium among the ^{234}U and ^{238}U isotopes is attributable to the excess of ^{234}U related both to the recoil effect, and the preferential leaching of ^{234}U respect to ^{238}U by acidic waters from minerals in the mining areas. A range between 0,056 mBq/L and 0,169 mBq/L for ^{230}Th activity, whose presence in solution is mainly related to the decay of ^{234}U , was obtained. Its presence in solution again comes from the acidic environment that promotes the desorption of thorium from particles and colloids, as well as mineral phases undergo dissolution.

INTRODUCTION

The Río Tinto is one of the most important in the Huelva province, with a basin extended for 1676 km² and a length of about 100 km before reaching the Ría de Huelva estuary. It is well-known for its red coloured water, that gives it its name. Archaeological studies estimate the Río Tinto mining district has been exploited since 4500 years, first of all by the local population, then from Tartars and Phoenicians. It's since Roman Age that mining activity became more developed together with pollution increased (high Pb content was detected in ice level in Greenland, dated back to Roman age with isotopic compositions revealing that 70% of its contain came from Río Tinto mine); later, excavation activity decreased until the XIX century, when industrial revolution occurred and mining activity rose again, such a step provoked extreme damage to the environment due to the hundreds of mines that were operating during XIX and XX centuries producing sulphuric acid, copper and other base metals like Zn and Pb. The Río Tinto rises in Peña de Hierro, a mine located to the north-east of Río Tinto anticline. Even if it is less known respect to the Río Tinto mine and it dates Roman age, Peña de Hierro has a higher metal grade and it started to be profitable during the early XIX century, when several mining companies turned exploiting it. Like other mines advanced in Spain, it's located in the Iberian Pyritic Belt, rich in massive sulphide deposits, and Río Tinto path-flow is almost entirely delineated thru this area. The most common sulphide is pyrite (FeS₂), but it's associated with minerals of economic interest like chalcopyrite (CuFeS₂), sphalerite (ZnS), galena (PbS), arsenopyrite (FeAsS), etc.

The weathering on these sulphides during the last century caused the pH to fall down to values <2, favourable to the mobilization of heavy metals and natural radionuclides in waters and sediments (Borrego et al., 2001; Sánchez España et al., 2005; Hierro et al., 2011; Ketterer et al., 2011). Several studies were developed on this peculiar subject, with evidence of very high values of uranium concentration in acidic waters. As an example, Ketterer et al. (2011) revealed that dissolved ²³⁸U activity varies from 10 to 850 mBq/L, with the highest ²³⁸U activities and the highest ²³⁴U/²³⁸U ratios observed under the most acidic conditions.

All the processes of transfer materials from the continents to the oceans are constrained by the removal of reactive elements on to particles (Turekian, 1977). The *scavenging* process is the one by which elements are subtracted from dissolved form to particulate or colloidal form. It depends on particles composition and the probability of changing in its form is function of contact surface between particles and dissolved species, so it will be more significant in particles-rich environments, as those developing in acid mine drainage (AMD) conditions where colloids are very abundant due to the precipitation of Fe-oxyhydroxides and secondary sulphates as pH rises. Easy-absorbable elements and with low solubility will quickly remove from the water and will be deposited within the sediments, whereas elements which have the same residence time as mixing-time will be transported horizontally within to the particles-flow. Different results came out respect to the distinct affinity for sorption onto particles of each element (Osthols, 1995; Balistrieri et al., 1981; Lao et al., 1993), due to the scavenging residence times depending on composition and other uncontrollable factors. Chase et al. (2002) and Luo & Ku (2004) tried to go beyond this problem defining a partition coefficient which depends on the composition and describes the equilibrium partitioning of a species between the dissolved and the particulate phase. The dynamics of the system that regulate the delivery of the metals in the waters have been widely studied even though it's not always possible to study directly all of the elements.

Scientists have been able to carry out information thanks to the investigation on elements with similar physical-chemical behaviour or using tools such as ^{238}U - ^{234}Th disequilibria to understand, for example, removal of Th.

Secondary minerals forming in acid mine drainage system are critical because of the increasing in the capacity for adsorption due to high surface area of the precipitation of Fe-oxyhydroxides phases (Jamieson et al., 2015). The latter are crystalline and amorphous colloidal forms that play an important role in acid rock drainage as carrier of metals and radioisotopes. Colloidal particles can be regarded as an intermediate of the precipitate formation process, since results show that only the degree of crystallization increases when particles are transformed into precipitates (Zänker et al., 2002). Nordstrom (2011) concluded that Fe(III), which is the major oxidant of pyrite under acid conditions, complicate the interpretation of dissolved concentrations species due to its colloidal form that passes through most filter membranes and alters the results respect to dissolved Fe(III). This phenomenon was pointed out in other works (Jamieson et al., 2005; Wang, 2014) who confirm that, high colloidal-content lead to an overestimation on the Fe-content and its associated elements. In acid drainage conditions, like in Río Tinto area, the abundant Fe-content colloidal fraction has high ability in ions absorption, and this fact was recognized by several authors (Dold & Fontboté, 2002; Andersson et al., 2001; Chen et al., 2001).

Aim of the work

Colloids act like ligands that influence speciation, removal, transport, bioavailability and toxicity of trace elements in aquatic system (Doucet et al., 2007), nevertheless their study is complicated because of its nature, since their instability, their minute size, their low concentration, their heterogeneous composition, their tendency to form carbonated complexes or to associate with clay minerals and their closed association with organic material (Lead & Wilkinson, 2007; Filella, 2007). That's why Río Tinto area is a perfect site for studying the influence of colloids on the dynamics of the system, since the following points:

- 1) In the Río Tinto prevailing conditions, pH neutralization, which occurs when strongly contaminated water get in touch with clear water from precipitation or of no-contaminated tributary, leads to the formation of the colloids, which result rich in sulphate complexes and ferric and/or aluminium disulphates.
- 2) At these conditions, colloids concentration tends to be very high due to the extreme ligands concentrations in the contaminated water.
- 3) There is no carbonate or bicarbonate dissolved in the acid water of Río Tinto basin.
- 4) At so low pH order, organic matter may be considered negligible.

All of these aspects make Río Tinto conditions ideal to assess the role of colloidal particles on the carriage of significant amount of radionuclides and to evaluate their role on the natural remediation of the system. To achieve this goal, ultrafiltration experiments on collected water samples was developed using 50 kDa, 10 kDa, 5 kDa and 3 kDa membranes. U and Th were investigated, measuring their activities for each of the samples obtained. Lastly, a permeation model was established for the discussed elements.

1 - STUDY AREA

The study area is located in the south-west of Spain, in the mining district of Río Tinto (fig. 1). Río Tinto is the name of a river that rises in Peña de Hierro, next to Nerva, in the north-east of the Huelva province and flows across the Iberian Pyrite Belt, one of the most relevant volcanogenic massive sulphide district in the world. The study was developed to a close area of approximately 60 m², delimited by a big tailing of the Peña de Hierro mine to the west, the headwaters of the Río Tinto to the north, the slope coming down the HV-5011 road to the east and the street that goes from the HV-5011 to the Peña de Hierro mine entrance on the south. In this restricted basin, Río Tinto water catch two different water contributions: one of them arises from the tailing dump and flows along the west-side into the Río Tinto, whereas the other one join the segment resulted by this first water mixing about 7 m further to the south than the first one, but running from the east-side of Río Tinto and generating another mixing.

1.1 Geological setting

The investigated zone is included in the 1:50000 sheet number 938 (Nerva), resulted from the MAGNA project (NAtional Geological MAP) conducted between 1972 and 2003 by the Spanish Geological Survey (IGME), and situated in the central-east part of the Huelva province, in Sierra de Aracena foothill. It's located in the eastern extremity of the Iberian Pyrite Belt, which is extended from the Baixo Alentejo province in Portugal towards the Spain with a NW-SE direction, forming an arch 240 km long and 35 km wide that belongs to the South-Portuguese Zone, the southernmost domain of the Iberian Massif. The area is characterized by deposits dated back to Upper Devonian and Lower Carboniferous, that can be resumed in a relatively simple succession, shown in the schematic section in fig. 2: the Devonian Phyllite and Quartzite Group (PQ), the Volcano-Sedimentary Complex (CVS) and a Carboniferous flyschoid sequence named the Culm formation, that is the base of the Baixo Alentejo Flysch Group (the following Carboniferous component of the South-Portuguese Zone) but included in this domain. The oldest rocks observed are organized in the PQ group and they consist in a detrital sequence of more than 2000 m of slate alternated with sandstones, with facies revealing a stable continental shallow platform deposition during the Frasnian and Famennian ages. Formation of half-graben basins, related to the Hercinian compressive tectonic just started, led to a period of instability in which, heterogeneous and high energy sedimentation prevailed, determining the deposition of subaerial, delta fan and gravity flows deposits, recorded now in the PQ hanging wall and representing the Famennian transition with the overlying Volcano-Sedimentary Complex (VSC) (Moreno et al., 1996). The VSC include a complex bimodal volcanic unit intercalated with shales, volcanogenic facies and Mn-rich chert deposits of late Famennian-middle Viséan ages. The activity was submarine and, despite the fact that it is a discontinuous unit and it varies frequently and quickly both in thickness and in lateral and vertical facies distribution, it can be differentiated in two felsic volcanic cycles separated by two mafic cycles. On a regional scale, the unit hold a Mn-rich bed of purple shale associated to jasper and forming a continuous marker in the uppermost part of the succession. The thickness range of VSC is 0-1300 m, due to the differences in the intensity of the volcanism within the intracontinental basin wherein it occurred, and the characteristics of the northern domain widely differ from those of the southern domain. The latter reflects a continental influence deposition, proved

B, stratigraphic sections of the northern and central members of the Iberian Pyrite Belt. From Franklin et al.(2005).

by the abundance of shale and siliciclastic sediments, whereas the northern area shows a thick volcanic sequence with lower content in shale. Felsic terms dominate, with andesitic-rhyolitic range composition (with a prevalence of the dacitic one) of the formed domes and sills and their associated volcanoclastic deposits, constituted by hyaloclastites and pumice- and glass-rich rocks. These rocks are calc-alkaline with low Al-content and high Nb-content, though the less common mafic rocks consist in tholeiitic and alkaline basaltic and andesitic-basaltic lava flows and pillow-lavas (Mitjavila et al., 1997). Volcanoclastic rocks occupy low topographic places and they are interpreted as resulting from the dismantling of the volcanic structures, which were building up meanwhile the interaction with sea-water. The massive sulphide deposits of the Iberian Pyrite Belt are enclosed in the VSC (fig. 3) and orebodies show distinct relationships with their host rocks. They reflect the previously described two domains of the succession, because of their paleogeographic control: the black slate-related are mainly spread in southern part, reflecting deposit formed in anoxic third-order basins, like brine pools, where the hydrothermal activity was very efficient despite the shortness of the time interval (less than 5 million years) during which the deposits were developed; the felsic volcanoclastic rocks-related are located in the north part and they were originated by the replacement of the below seafloor volcanic rocks. A submerged sedimentation environment has been proposed for the PQ Group and the VSC (Quesada, 1996; Sáez et al., 1996), but due to the different depths revealed by several depositional setting of rocks, Sáez et al. (1996) suggest the Iberian Pyrite Belt as including several deep basins separated from deeper zone and other emerged ones during the massive sulphide formation. In the Culm formation, that overlays VSC, shales and sandstones deposited from turbidity currents are the main lithologies. They have Carboniferous age (upper Visean) and their thickness reach 3000 m. The formation represents a sinorogenic flysch sedimentation related to the Variscan collision and their reversal tectonic (Moreno, 1993). All of the rocks constituting the IPB were metamorphosed and deformed by Variscan orogeny, so they suffered a regional low grade metamorphism in green-schist facies, that increase from the south to the north of the belt and towards the base of the sequence (Munhá, 1990), due to the subsequent intrusion of large granitic, tonalitic and dioritic bodies. The Variscan tectonic produced a *'thin-skinned'* deformation which affected the shallower part of the crust, developing a thrust and fold belt with a southward and south-westward vergence and the consequent foliations parallel to the folds structural axis oriented WNW-ESE. Other important manifested metamorphism is the hydrothermal one, resulted from the interaction between rocks and circulating fluids, heated by the anomalous geothermic conditions existing during the Upper Devonian and the Lower Carboniferous.

1.1.1 Metallogeny

Massive sulphide deposits occur within the VSC and exhibit the classical configuration of Volcanic Massive Sulphide deposit, that is a lens of massive sulphide superimposing a wide sector with rocks interested by an important hydrothermal alteration. *"Stockwork"* mineralization is disseminated in the body nucleus, it consists in a network of widespread sulphide-rich veins as a consequence of hydrothermal fluid flows exhaled out of the sea floor (fig. 4). Mineral paragenesis comprehends pyrite as the prevailing phase, with sphalerite, galena and chalcopyrite as accessories, together with many other minor minerals. These massive sulphide deposits can be grouped into two different styles of mineralization,

reflecting the formation in contrasting geological settings (Tornos, 2006). The southern part includes deposits that are in direct relationship with shale, sedimentary component prevailing in this sector of VSC, with features developed in a low-topographic zone suggesting an exhalative environment evolved in third order basins: this kind of basins, with their reduced extension, their euxinic and low-energy deposition that build-up organic-rich, pyritic, fine-grained shale and mudstone, it is the best environment providing ideal bathymetric and chemical conditions for dense, sea-floor-closely, metalliferous and sulphur-depleted upwelling brine to accumulate and react with locally H₂S derived from sulphur-rich seawater, so as to lead to the precipitation of the sulphide minerals that compose the ore. These massive sulphides are characterized by a high (10-20) aspect ratio (longitude/thickness) due to their stratiform morphology, large tonnages, abundance of pyrite but low total base metal content, abundance of sedimentary structures but absence of sulphate. The sulphides are composed by fine-grained anhedral to subhedral pyrite, with interstitial sphalerite, chalcopyrite and galena. Carbonates are also present as widespread siderite-cemented breccias (Tornos & Conde, 2002) or as a pervasive ankerite-rich hydrothermal alteration. Other characteristic features are the presence of a large underlying stockwork and no evidence of clear metal zonation. Northern part deposits are hosted in a felsic volcanoclastic sequence with low level of mudstone, so they are poor in sedimentary structures. They show replacive fronts on felsic volcanic rocks and a hydrothermal alteration around the massive sulphides. The most recent model proposes these massive sulphides are formed by replacement of the sub-seafloor volcanic rocks, explaining their greater base metal richness with the efficiency of the geochemical trap of this environment (Doyle and Allen, 2003). They are hosted by high-energy volcanoclastic rocks like transported hyaloclastites or pumice/crystals/glass-rich breccias. At regional scale, the formation of massive sulphides was determined by the Variscan '*thin-skinned*' tectonic that furthered intrusion of basic magmas into the crust: these conditions let the geothermal gradient increase, as well as they led to acid magmas production and aided diagenetic and metamorphic evolution of the PQ group with the expulsion of saline water fluids full of metals in the convective cells generated by acid magma intrusions. As like as the southern shale-related deposits, the distribution of the massive sulphides follows the regional setting, so they are clustered along E-W trending zones forming isolated groups. The regime developed stacking lens of these massive sulphides, giving rise to intermediate (5-10) aspect ratio deposits, that present generalized recrystallization due to their intense deformation and a host rock with a pervasively silicic and sericitic alteration. Northern deposits are rich in sphalerite, galena, tetrahedrite and gold, they typically contain sulphates like barite and gypsum and oxides like magnetite. Grain size ranges from medium to coarse and remnants of silicified and chloritized host rocks are frequent within whole deposits. Tectonic banding is determined by distinct sulphur-enrichments layers alternation; such an origin is moreover confirmed with the existence of widespread S-C structures, composition and texture of banding, as well as the presence of angular fragments of pyrite hosted by the more ductile sphalerite-galena matrix. Here the metal zonation is well-defined and show differentiated Cu- and/or Zn-/Pb-rich zones. The supergene alteration of these massive sulphides originated large gossan outcrops, usually enriched in Au and Ag, but without showing any obvious zoning.

Fig. 4 - Stockwork mineralization in pyrite (a) , highlighted by the oxidation. In detail (b) the small minerals are disseminated in a network of widespread veins.

Fig. 5 – A) Branch of water flowing from the big waste pile of Peña de Hierro mine. B) The drainage in this area is developed in shale, prevailing sedimentary component that, together with all of the rocks of the IPB, suffered the Variscan orogeny

Fig. 6 – Ochre and brownish coloured precipitated typical of the acid mine drainage sites.

Fig. 7 – Acid mine drainage (AMD) contamination starts with the oxidation of pyrite and goes on with a series of reactions that release more and more acidity, sulphate and an elevated amount of metals and metalloids, leading to a toxic and highly contaminant solution (a e b). When pH rises, precipitation of Fe-oxyhydroxides and secondary sulphates occurs, developing a particles-rich environment characteristic of AMD conditions (c). In d: efflorescent sulphates formed in the course of a dry period that temporarily store acidity, SO_4 and metals.

1.1.2 *Río Tinto district*

Río Tinto synclinal is a Carboniferous structure with W-E direction, with a main gentle folding and several minor folding, one of whom constitutes the Río Tinto volcanic anticline with its related mineralization. Faults and thrust are abundantly present, together with a pervasive hydrothermal alteration often hiding original formational relationships. In Río Tinto district we can find deposits showing both northern and southern characteristics, reflecting their different original environment, in fact the mineralization in Northern Vein is dacite-hosted displaying replacement structures with it, while the one of Southern Lode is slate-related (fig. 5) and has sedimentary structures formed in a exhalative scene. So we get the mineralization as disseminated or in small veins in the stockwork areas, as well as in lenses in massive form above or comprehended in the stockwork zone, or in gossan area representing the supergene alteration.

1.2 **Geochemistry of the acid mine drainage**

1.2.1 *AMD contamination*

A common aspect of the study area is the pervasive presence of yellow-ochre to reddish-brown sediments in the riverbanks, consisting of Fe-precipitated due to the pyrite oxidation in mine sites (fig. 6). In reducing conditions sulphides are extremely insoluble. They remain stable in the subsoil as long as they don't react with oxygen, but once they get in touch with it and with water, the oxidation of pyrite takes place:

This reaction origins acidity (H^+) and produces a large amount of sulphate (SO_4^{2-}) and ferrous iron (Fe^{2+}), leading to a toxic leached solution with an extreme contaminant capacity. However, when ferrous iron (Fe^{2+}) flows over the contact surface with the oxygen, oxidation to ferric iron (Fe^{3+}) occurs, according to the following reaction:

this reaction is catalysed by bacteria which increase the rate of the reaction by a factor of 10^6 .

Ferric iron (Fe^{3+}) can persist as dissolved form at $\text{pH} < 3$ or it can precipitate as Fe-hydroxide producing more acidity:

1.2.2 *AMD chemistry*

As seen above, Fe^{3+} and hydroxides precipitated give the typical red/yellow colour to the rivers affected by this process, as typically manifested in acid mine drainage rivers. Further, oxidation of accessory sulphides (e.g. As or Se in pyrite; Co and Ni in pyrrhotite) takes place

and an elevated amount of metals and metalloids like Cd, Cu, Pb, Zn, etc., some of them extremely toxic, are released. In the literature several case studies reporting the typical AMD chemical composition of waters draining massive sulphide deposits can be found, all of them suggesting a strong geologic control on its chemistry dictated by the deposit geology and mineralogy (Ball & Nordstrom, 1989; Goldfarb et al., 1996; Plumlee et al., 1999; Nordstrom & Alpers, 1999). One more interesting feature of the AMD chemical composition is the high U and Th contents. Studies demonstrated the good correlations between U and elements such as Al, Mg, Mn, and Zn, Cd and SO₄, whom suggest that U could be derived 1) from the dissolution of aluminosilicates of the acidic volcanic lithologies present in the area and 2) other phases related with sphalerite-rich complex ores (Sánchez España et al., 2005). The concentration of metals in the acid solutions decreases the further you move away from the discharge point, since their co-precipitation with Fe-oxyhydroxides that always formed due to solution supersaturation in Fe, though this acidic leached reacts with the surrounding rocks and produces dissolution by hydrolysis of other gangue minerals. This explains the abundance of elements like Al, Ca, Mg, Na and K in acid mine waters. These reactions, normally very slow, are catalysed by microorganisms, identified by several microbiological studies (López-Archilla & Amils, 1999; López-Archilla et al., 2000; González-Toril et al., 2003) as chemolithotrophic acidophilus bacteria that use minerals as their source of energy in addition to elements from atmosphere. In fact, sulphide oxidation would not be a problem without these bacteria, since the produced acidity could be neutralized by the environment. Field and laboratory investigations confirm that the oxidation rates measured in sectors with dense biofilms of acidic slime streamers are remarkably faster than those measured in sites where streamers are not present (Nordstrom, 1985; Williamson et al., 1992; Kirby & Elder Brady, 1998; Kirby et al., 1999; Sánchez España et al., 2007). In acidic conditions, they will reproduce very fast and the consequence will be an increasing in acidity in order to generate a negative feedback system, with a leached solution characterized by very low pH and very high metals and metalloids concentration. Anyway, the composition of AMD suffers seasonal variations: during the summer, a lower flow rate and a decrease in pH are observed, so they could be factors in determining the changing in elements concentrations. Efflorescent sulphates form in the course of the dry period (fig. 7), so they act like a temporal store of acidity, SO₄ and metals that will be dissolved in the more raining winter, determining increase in acidity, SO₄ and metals content (Sánchez España et al., 2005).

1.2.3 Anthropic effects

The anthropic activity strongly accelerated the natural oxidation of pyrite due to actions linked to the mining activity. Mineral resources exploitation involves different workings settings, each of them leads to an increase in the surface area exposed to the oxidation. Looking to an update of Nordstrom et al. (2015), the anthropic impact on the drainage water can be appreciated. For example, underground workings is a mining technique made up of various features, excavated usually into relatively intact rock in order to gain access to the orebody. Blasting and collapses of the wall-rock develop uneven unsheltered surfaces, together with widespread fracture networks, that carry out enlarged revealed surface areas in contact with water and oxygen. The increase in the reactive surfaces causes an increase in the sulphide oxidation and in the rate of the release of leached solution into mine waters. The difference between this technique and open-pit operations is that the latter are developed to extract near-surface orebodies and are made of a series of benches that allow

the stability of the pit walls. During mining activities, operations of dewatering are necessary, so they conduct to the uncovering of the pit-walls. Because they are irregular and fractured as well, the consequence is the same: more sulphide minerals and gangue minerals exposed to water and oxygen and more release of dissolved components into mine waters. The closure of an open-pit carries out a pit lake, wherein atmospheric water and groundwater will be collected, together with the previously stocked oxidation products that will impact water quality. Another problem affecting mine sites is the generation of big amount of waste, like the finely ground tailings and waste-rock piles. Meteoric water drains these accumulations but interacts with them differently: if the fine grained nature of the tailings limits the rate of the infiltration water, in the heterogeneous waste rock piles water can flow through interconnected pores. Therein, interactions between infiltrate water, gas and solute take place, thus they become an important controlling factor in the piles drainage. Since the sulphide oxidation, which is also influenced by external forcing that acts on temperature and gas characteristic of the pile (Amos et al., 2009), is an exothermic reaction, the generated heat can establish thermally driven convective gas-transport cells, by which oxygen can be transferred deep inside the waste pile with the consequence that a greater volume of rock undergoes oxidation (i.e., Lefebvre et al., 2001; Ritchie, 2003). Then, oxidation products within the pile interact with other minerals in the waste (Smith et al., 2013) and can either neutralize acidic pore water or form secondary minerals and gases along flow path. The same reactions happen in mill tailing, but downward and laterally through the tailings.

1.3 Uranium

Uranium is a strong lithophile element, which means that it is concentrated in the silicate minerals of the crust, and it has affinity with the oxygen occurring often in the oxide minerals too. Despite the fact that uranium is the highest number element found naturally on Earth, it's not so uncommon as it was thought and it can be found associated with other minerals. The average abundance of uranium in the Earth's crust is estimated varying between about 2 and 4 ppm, similar to the values of arsenic or molybdenum, but higher than elements like silver, mercury or cadmium, with higher values in acidic igneous rocks and minor amount in the basic ones. Average U content in granites amounts to 4,5 ppm, while in peridotites is up to two orders lower. The range for metamorphic rocks is 0,5-3,0 ppm. Shale are the sedimentary rocks containing more uranium than others, reaching a 3,5 ppm content (Gupta & Singh, 2003), while the value that can be found in the literature about its concentration in seawater is 3,3 ppb (e.g. Ku et al., 1977) and in common surface waters it presents temporal and spatial variability strongly dependent on the local redox conditions (Plater et al., 1991). The most common valence states of uranium are the tetravalent (IV) and the hexavalent (VI) states, even if it exists until the bivalent form, then the best-known minerals containing tetravalent uranium are uraninite and pitchblende, oxides having different content in UO_2 , that form uranium ore deposits. Other important uranium minerals are phosphates like autunite and torbernite, simple and hydrated silicates like coffinite, uranothorite and uranophane, as well as vanadates and arsenates like carnotite and zeunerite respectively. Uranium is a radioactive element occurring with different isotopes, two of whom ^{238}U and ^{235}U , have long half-life ($4,471 \times 10^9$ y and $7,04 \times 10^8$ y respectively) and establish U-series radioactive disequilibria, a very widely used tool for dating a variety of processes. Isotopic studies of U in river waters were undertaken and it has been suggested

that the U isotopic ratios of river waters could depend on the lithological nature of the formations constituting the watersheds (Sarin et al., 1990; Plater et al., 1992); therefore, $^{234}\text{U}/^{238}\text{U}$ activity ratios could be very useful to investigate hydrological processes and as tracers of rock weathering (Riotte & Chabaux, 1999).

1.4 Thorium

The abundance of thorium in the Earth's crust is relatively high, it amounts to 6 ppm. Monazite and thorite, a phosphate and a silicate respectively, are the most common ores of thorium, though this element occurs in uranothorite, thorianite and it can be found as significant trace element in minerals like zircon, titanite, gadolinite and betafite. Thorium is composed of several isotopes, all of them radioactive with different half-lives: 24 days for ^{234}Th , 1,9 years for ^{228}Th , $7,5 \times 10^4$ years for ^{230}Th . The most stable isotope is ^{232}Th , which represents almost all naturally occurring uranium, with a half-life of 14,05 billion years after which it decays in radium by alpha-decay and can go on in its decay chain, until the stable ^{208}Pb . The fact that Th(IV) is the only stable oxidation state under all redox conditions in natural waters, and that these ions are extremely particle reactive, makes Th a very useful tracer of several oceanographic processes (Santschi et al., 2006). It is a strongly insoluble element in a wide variety of environmental conditions, indeed ^{232}Th concentration in seawater amounts to pM order, further other Th isotopes, e.g. ^{234}Th , ^{230}Th , ^{228}Th , are also present in seawater at very low concentration, due primarily to natural radioactive decay of uranium isotopes that are soluble in seawater (Bacon & Anderson, 1982; Moore, 1981). Its solubility is high in hydrochloric acid, at room temperature thorium reacts not so quickly with oxygen, in contrast to higher temperatures conditions where it reacts with oxygen faster, forming thorium dioxide (ThO_2) which has the highest melting point of any oxide (3300°C). Thorium in natural waters is typically complexed with inorganic ligands, such as sulphate, fluoride, phosphate and hydroxide, as well as with organic anions, all of which lead to the increase of the solubility of Th minerals and the mobility of this elements in surface (Langmuir & Herman, 1980). Thorium can be present in solution as Th^{4+} only in very acidic waters (Rai & Serne, 1978).

1.5 U-series

Weathering usually fractionates U-series nuclides determining the radioactive disequilibria in the decay chain. Chabaux et al. (2008) summarize the three main parameters which come into play on the behaviour of U-series nuclides in natural waters:

- 1) the chemical speciation of radionuclides in solution
- 2) their interactions with mineral and organic solids
- 3) their reactions with colloids.

1.5.1 Chemical speciation of radionuclides in solution

The chemical speciation of uranium in solution has been extensively studied and depends on redox conditions, pH and aqueous solution composition (fig. 8).

Uranium in natural water is usually complexed with inorganic ligands like phosphate, sulphate and fluoride, as well as carbonates and organic ligands, all forms that enhance its

solubility; so this ability of uranium to form complexes influences dissolution, sorption on minerals and colloids surface and the form in which U may precipitate. Among the two more frequent form, the hexavalent one has the highest mobility in the environment in the form of UO_2^{2+} , while U(IV) is stable in extremely reducing conditions for $\text{pH} < 5$.

Fig. 8 - Eh-pH diagram for the system U-C-H-O at 25° and 1 atm with $\Sigma\text{U} = 1 \text{ mm/L}$ and $P_{\text{CO}_2} = 10^{-2} \text{ atm}$ (from Langmuir, 1978)

Thermodynamic data show that even U(V) as UO_2^+ has a considerable field of stability in reduced water, resulting in a vastly increase of the mobility of uranium for a wide range of natural conditions. During water-rock interactions and their transport in solution, each of other nuclides of the U-series behave differently than U: for instance, Th is known to be a very insoluble element for $\text{pH} > 3$. This variability can led to significant geochemical fractionation among these nuclides, since, except in highly reducing or highly ligand-rich solutions, fluid phase will be generally enriched in U and the residual solid phases in Th (Chabeaux et al., 2008).

1.5.2 Interactions with solids

The mobility in solution of radionuclides is controlled by their reactivity with mineral surfaces and organic compounds. Carbonate anions form strong complexes with actinides in solution, consequently carbonate minerals are the best to make their surfaces available for actinide sorption. But in general the entity of this process depends on the nature of nuclide and of the interacting solids. Duff et al. (2002) show how the adsorption on mineral surfaces is controlled by mechanisms like surface complex formation, precipitation of U-bearing phases on mineral surfaces as well as structural incorporation of U in mineral host phase. Concentration of radionuclides takes an important role in their removing from solution by adsorption on minerals, because of its influences on the way how the radionuclides can be incorporated, together with the mineral growth rate and the bacterial activity.

1.5.3 Reactions with colloids

Colloids have an important influence in determining the mobility of U-series nuclides, especially of U and Th, because their presence, both as organic and inorganic form, modify the metal ion sorption onto mineral surfaces. More details are illustrated in the section 1.6.

1.5.4 Recoil

The fractionation of the U-series nuclides in solution can also take place due to a process induced by radioactive decay called "recoil". This process is defined as the motion acquired by an atomic nucleus during its emission of particles in radioactive decay, or during its collision with another particle, and determine a displacement called recoil range(δ) whose entity depends on the decay energy and the density of the solid phase. Typical values of the recoil range in mineral phases vary between 40 and 70 nm, but in air will amount up to 50 μm (three orders of magnitude larger). This displacement is influenced by grain size(r) and the difference in range has important consequences for the mobilization of daughter nuclide: when the grain size is large ($\delta/r \ll 1$) the effect will be negligible, while if the grain size is small the recoil will fractionate significantly the parent nuclide and its daughter. For example, let's take in account a $\delta = 19$ nm for quartz, with the decay of ^{238}U that produces ^{234}Th . If it happens in sand with a grain size of 250 μm , the ejection factor (that is the fraction of daughter atoms ejected relative to that produced) will results in $7,6 \times 10^{-5}$. If it happens in silt or in clay, having grain radius $r = 30$ μm and $r = 1$ μm respectively, the ejection factor will be $6,3 \times 10^{-3}$ and $1,9 \times 10^{-2}$ respectively, with the latter that becomes significant. Other complications may come out based on the saturation of the porous medium and on the distribution of the parent nuclides. Thereby the amount of recoil nuclides that are effectively reject into solution will depend strongly on these factors, as well as on the surface from which daughter nuclides can be expelled. Another aspect to be mentioned was suggested by Kigoshi (1971) and was experimented by Fleischer (1982, 1983, 1988): even if these recoil nuclides are not emitted in the pore spaces, their displacement due to recoil makes them more easily to be removed from their sites in the mineral, so they are preferentially leached and the shorter-lived nuclides they are, the more is the leaching efficiency because if the leaching occurs in a time-scale longer than the time required for the annealing, it will be not efficient (Eyal & Olander, 1990).

1.6 U-series disequilibria in rivers

In rivers, weathering controls the fractionation and it is the main player governing the mass balance, since it provides the new bedrock material weathered as input in the system, as well as it provides the output represented by dissolved and weathered particulate material. Regardless the uranium in the bedrock, we need to assume that $^{234}\text{U}/^{238}\text{U}$ activity ratio is in secular equilibrium to affirm that in a steady-state context these two elements are equal; under secular equilibrium, the activity of the parent radionuclide undergoes insignificant changes during the half-life of its decay products. If it is not in secular equilibrium, it is necessary to take into account the contribution of daughter nuclides given by the uranium decay. ^{234}U - ^{238}U disequilibrium is related to the recoil process, which causes release of ^{238}U

decay product from the solid into the solution and the perturbation of the crystal network where ^{234}U is located, promoting preferential leaching of ^{234}U respect to ^{238}U . This process is time-dependent, this is the reason why U-series disequilibrium is an excellent tool and a chronometer of weathering processes. U-series disequilibrium in rivers gives information about weathering processes at the scale of watershed (Chabaux et al., 2008), so U-series isotope analyses have been used to investigate various issues, such as the contribution of rivers to the seawater U budget (Sarin et al., 1990), the behaviour of U-series isotopes during weathering and transport in rivers (Plater et al., 1992; Porcelli et al., 1997; Andersson et al., 1998) or the sources of dissolved flux, in particular groundwater contributions (Riotte & Chabaux, 1999; Riotte et al., 2003), as well as the nature of erosion, the estimation of its timescale and its related sediments production and transport rates (Dosseto et al., 2006). The control of the intensity of weathering on the magnitude of $^{234}\text{U}/^{238}\text{U}$ activity ratios of river waters was proved by Robinson et al. (2004), while Sarin et al. (1990) observed the control of the lithology on the $^{234}\text{U}/^{238}\text{U}$ fractionation during rock weathering. Uranium concentration in rainwater range from 0,5 ng/L to 50 ng/L, so U input from the atmosphere to rivers is generally considered insignificant. However, other potential sources of U nuclides in the environments are anthropic activities. Further processes called for the explanation of anomalous activity ratios are adsorption of dissolved radionuclides onto particles (Chabeaux et al., 2008), or mobilization of particulate Th through complexation with organic colloids (Plater et al., 1992; Dosseto et al., 2006). Organic and inorganic colloids are an important component of the $< 0,2 \mu\text{m}$ fraction and play a critical role in Th and U mobility (Swarzenski et al., 1995) and thereby on radioactive disequilibria (Dosseto et al., 2006).

1.7 Fundamentals of colloids

The exact definition of colloids has been discussed for many years and it is still debated because of nomenclature divergences in view of different disciplines involved in their study. Environmental colloids are relative dilute dispersion of solid phase (sometimes liquid or gas) within a water or atmospheric gas (Lead & Wilkinson, 2007). Regard to a size-based definition, colloids can be conventionally defined as dispersed phase with sizes ranging between 1 nm and 1000 nm, boundaries that though are not so rigid (Everett, 1998). Thus they are macromolecules and nanoparticles with the upper size limit that shall be considered as the point at which particle-particle interactions are no longer dominated by Brownian motion, whereas the lower limit is more vague since it depend on the chemical species. Then, as can be seen in fig. 9, colloids in aquatic system comprehend macromolecular organic matter, microorganisms, viruses, aggregates and nanoparticles such as clay minerals and oxides of iron, aluminium and manganese coated with or sorbed on organic matter (Guo & Santschi, 1997; Buffle et al., 1998; Gustafsson et al., 2000; Taillefert et al., 2000).

The most common inorganic colloids found in oxic waters are aluminosilicates, silica and iron oxyhydroxyde particles (Pizarro et al., 1995; Buffle et al., 1998). In circum-neutral pH range, the majority of them have low zero point charge so they are negatively charged, excepting Fe-oxyhydroxydes with them neutral or positive charge (fig. 10). But this is not the case of Río Tinto area, where pH values are very low with the consequent elevated zeta potential values for amorphous oxy-hydroxides of iron and aluminium, that keep this colloidal system in a stable state. The other inorganic colloids change in positively charged with low zeta

potential value, then repulsion forces are not so strong, so they get the ability to come together catching other particles to growth in an aggregate. For natural nanoparticles, its nucleation is related to a geological fluid that becomes supersaturated with a mineral phase. For a given saturation degree (Ω), the critical size of nuclei (r^*) is determined by

$$r^* = \frac{2\gamma V_m}{RT \ln \Omega}$$

where γ is the surface energy, V_m is the volume of a formula unit of the solid, R is the gas constant, T is the absolute temperature (Steeffel & Van Cappellen, 1990). Consequently, for a given mineral phase, the higher is the saturation degree, the smaller is the particle size.

Fig. 9 - Size spectrum of chemical species in aquatic system. From Guo & Santschi (2007), reproduced from Wen et al. (1999).

| nature of solid | pH _{zpc} | site density ^c (nm ⁻²) | specific surface area (m ² g ⁻¹) |
|-----------------------------------|----------------------|---|---|
| am-SiO ₂ | 3.0–3.5 | 4.5–12 | 40–260 |
| am-FeOOH | 7.9–8.1 | 0.1–0.9 mol/mol of Fe | 160–700 |
| am-Al ₂ O ₃ | ≈9.4 | 2–12 ^d | |
| am-MnO ₂ | ≈2.3 | 6–20 ^d | 260 |
| allophanes | | 0.4–1.2 | 500–700 |
| kaolinite | 3.3–4.6 ^b | 0.6–3.6 | 10–20 |
| chlorite | | 0.6–2.4 | 92–97 |
| illite | | 0.9–2.7 | 90–130 |
| smectites | ≤2.5 ^b | 0.5–1.0 | 750–800 |
| vermiculites | | 0.9–1.6 | 750–800 |

^a Values are taken from refs 6 and 26. Values are given for amorphous phases of metal oxides that should be more representative of natural colloids. ^b Values of pH at the isoelectric point and not at the zero point of charge (=pH_{zpc}). ^c Site density corresponds to the maximum negative charge density for pH >> pH_{zpc}. ^d Values for crystalline forms of Al₂O₃ or MnO₂.

Fig. 10 - Characteristics of inorganic colloids

1.7.1 Previous data.

Aquatic colloids are abundant in natural waters, so various works have been focused on their isolation and characterization (Guo & Santschi, 2007 and references therein). To know the partition of different elements between dissolved and colloidal phase, the most frequently used technique is the tangential (or cross-flow) ultrafiltration, by which it could be possible collect information about the concentration and the behaviour in different environments (e.g. Guo & Santschi, 1996; Gustafsson et al., 1996; Guo et al., 2000; Guo et al., 2001;). This technique will be exposed in section 2.2.1.

Previous studies demonstrated how U is associated with large particles and colloids (Porcelli et al., 1997; Andersson et al., 1998; Andersson et al., 2001). Andersson et al. (1998) found high concentration of Fe in river and brackish particles showing a strongly enrichment in U, especially related to the secondary Fe-oxyhydroxides, that, on the contrary of the Mn-oxyhydroxides, are largely responsible for the particle uptake of U. Even if U is highly soluble, they reported its different behaviour controlled by the differences in abundance and composition of colloidal fractions at different stage of changing in conditions of the system. However, the isotope composition is generally controlled by a significant isotopic exchange developed in a mineral-fluid system among their isotopes, as was suggested by Henderson & Burton (1999) and Dosseto et al. (2006). In their work, they show that isotope equilibrium will be achieved according to the transport rate (diffusion or surface reaction) relative to the advective transport time. Yamamoto et al. (2010) investigated radioactive disequilibrium in the uranium decay series in acid mine drainage system and in neutral surface waters from surrounding rivers in Japan, finding in the strongly acidic waters a high ^{238}U concentration, together with high concentrations of heavy metals, and an extremely high value of $^{234}\text{U}/^{238}\text{U}$ activity ratio (10-15). Here, ^{234}Th concentration was at similar level to that of ^{238}U , as expected as the result of its expulsion by recoil related to ^{238}U α -decay, and ^{230}Th is a daughter nuclide of ^{234}U , that instead was very low respect to its parent nuclide. Taking this into account, the authors concluded that deeper water is not in acidic condition, so the high $^{234}\text{U}/^{238}\text{U}$ activity ratio is probably due to the preferential leaching of ^{234}U , produced from the ^{234}Th adsorbed on the surface of mineral particles, in the underground water under neutral and reducing conditions. In addition, the elevated $^{234}\text{U}/^{238}\text{U}$ activity ratio could result if ^{234}U and ^{238}U are distributed differently within the solid matrix and if the ^{234}U is present in more labile sites, then preferential leaching of ^{234}U will be possible (Ketterer et al., 2011).

1.7.2 Colloidal uranium

Several investigations on colloidal U in natural waters were pursued, reporting considerable variability in the colloidal U percentage (table 1):

Table 1 - Reported colloidal uranium in natural waters

| Location | Salinity | U (nmol/kg) | size fraction | colloidal U (%) | reference |
|--------------|----------|---------------|------------------|-----------------|--------------------------|
| river waters | - | 0,076 ± 0,043 | 0,5 kDa - 10 kDa | 53 ± 10 | Tanazaki et al. (1992) |
| river waters | - | 0,076 ± 0,043 | 10 kDa – 0,45 µm | 12 ± 9 | Tanazaki et al. (1992) |
| Amazon river | 0,32 | 0,504 | 10 kDa – 0,45 µm | 83 | Swarzensky et al. (1995) |
| Amazon river | 9,74 | 1,85 | 10 kDa – 0,45 µm | 34 | Swarzensky et al. (1995) |
| Amazon shelf | 35,44 | 13,8 | 10 kDa – 0,45 µm | 14 | Swarzensky et al. (1995) |

Table 1- continued

| Location | Salinity | U (nmol/kg) | size fraction | colloidal U (%) | reference |

| Río Tinto | - | 4650 | > 5kDa | 9 | Casas-Ruiz & Barbero (2015) |

1.7.3 Colloidal thorium

Most of previous studies were developed on ^{234}Th distribution in marine environment, because of its peculiarities that make it a widely used tracer for natural processes, like biological or scavenging processes. It has a half-life of 24,1 days and it's produced in constant rate from ^{238}U dissolved in seawater. Furthermore this radionuclide associates strongly with particles. Organic marine collides have high affinity for hydrolytic trace elements such as Th(IV). Therefore Th isotopes of different half-lives may be used as natural tracers for the DOM cycling in marine environments (Baskaran et al., 1992; Guo et al., 1997; Chen et al., 2000). Detailed size fractionation of other Th isotopes in both dissolved and particulate phase is scarce, but it could be reported available results about ^{230}Th , useful for the aim of this work (table 2):

Table 2 - reported ^{230}Th data in natural waters.

| Regions | Phase | Salinity | ^{230}Th concentration(mBq/L) | reference |
|---------------------------|-----------|-----------|--|--------------------------|
| Narragansett Bay | Total | 26,4-32,2 | 0,07–0,27 | Santschi et al. (1979) |

2 - MATERIALS AND METHODS

2.1 Sampling and on-site analyses

To investigate the variations in water characteristics, the sampling was performed on 26 April 2016 at six different points: AC-1 from Río Tinto water before other water contribution; AC-2 drainage from waste pile of Peña de Hierro mine; AC-3 at the confluence of these two kind of water; AC-4 from the eastern natural river; AC-5 after this branch joins the just contaminated Río Tinto waters; AC-6 from a more upstream position along this branch, where life forms, e.g. frogs, and lush vegetation appear again. Sampling points are shown in fig. 11 e fig. 12. From each point, fifteen litres of water were collected in a 20 L polyethylene tank without filtration. The pH, Eh, conductivity and temperature was immediately measured with a calibrated multiparametric probe (Hanna equipped with probes HI 9025C, HI9033 and HI9025), resulting in the values listed in table 3, section 3.1. It was not necessary acidify the samples, because of no carbonate content of the water. Colorimetric analyses on iron content, chloride content and alkalinity were carried out on the most contaminated AC-2 water, testing an aliquot of it with Hanna Instruments Test Kits. For iron content, the reduction of all the Fe^{3+} to Fe^{2+} takes place by means of the reaction with sodium sulphate, resulting in an orange-coloured solution due to the mixing of fenantrolina with the ferrous iron; the intensity of the colour of the solution identify Fe-content, then, as expected, it resulted in the maximum intensity, testifying the extremely high concentration of Fe due to the waste pile leaching. Chloride content was detected using mercury nitrate, which reacts with chlorine ions to form mercury chloride; when Hg ions-content is too high, Diphenylcarbazine is added to form a violet solution, since this changing in colour determines the end of Cl counting. The amount set out for the test wasn't enough to reach violet colour, maybe because Cl could exist not as free ion but as complex compound (e.g. FeCl_2 , FeCl_3). Alkalinity test follows two steps: the Phenolphthalein Alkalinity measures total hydroxide ions content, after sample is neutralized at $\text{pH}=8,3$ using a dilute hydrochloric acid solution, with Phenolphthalein as indicator; the neutralization process convert hydroxide ions in water and carbonate ions in bicarbonate:

This measurement provides only half carbonate contribution because bicarbonate is converted in carbonic acid by adding hydrochloric acid. To obtain total conversion of bicarbonate, more hydrochloric acid is added since pH falls to 4,5 due to the following reaction:

giving back Total Alkalinity. It was not possible operate with this kind of water due to its too high Fe-content. The samples were transported to the Earth Science laboratory of the International Excellence Campus CEI-MAR, Faculty of Marine and Environmental Science, University of Cádiz, where subsequent experiments of ultrafiltration and isotopic analyses were carry on, starting with the day after.

Fig. 11 - Panoramic of study area and sampling point on Google earth image.

Fig. 12 - Pictures taken on-site during the sampling, showing the different collected water; a: AC-1; b: on-site measurement of AC-2 parameters; c: AC-4; d: it can be seen the change in colour after the water sampled as AC-4 joins Río Tinto waters; e: AC-6 sampling.

2.2 Ultrafiltration experiments

Collected samples were filtered using standard technique through a pre-cleaned 0,45 μm and 0,2 μm cellulose nitrate membrane into a pre-washed 20 L container, in order to isolate the coarser retained colloidal fraction for a future work on its characterization (fig. 13). To analyse the characteristics of the investigated elements in natural Río Tinto water with distinct size particle-content and how they could part between dissolved and colloidal phase, an amount of 0,2 μm filtered water of AC-1 sample underwent to ultrafiltration experiments. The restricted budget and the short time available for the analyses let us work only on just one of collected samples. Other samples will be further analysed by the active research team of the University of Cádiz that is still carrying on the projects wherein I took part.

2.2.1 Ultrafiltration procedure

A cross-flow ultrafiltration (CFUF) was performed on the selected pre-filtered water sample AC-1. This technique isolates colloids from the water in a relatively short time and provides the feed flow travels tangentially across the surface of the filter, with the main advantages that the substances detained by filter are constantly washing away preventing the filter-cake formation. The ultrafiltration system used is a Masterflex L/S system with a Vivaflow 200 PES (polyethersulfone) membrane with an active membrane area of 200 cm^2 (fig. 13). The Masterflex L/S peristaltic pump system includes fixed and variable speeds, with a flow range from 0,0006 to 3400 mL/min, that providing high accuracy drives for precise flow control. Setting the recirculation rate to approximately 300 mL/min, permeate flow rate results in 5 mL/min. All ultrafiltration experiments were performed in an acid-cleaned polycarbonate (PC) container and polyethylene (PE) tubing. In order to separate extremely small particles and dissolved molecules in fluids, different ultrafiltration membranes with different molecular weight cut-offs (MWCOs) were employed. The Vivaflow 200 membrane system was firstly pre-cleaned following the cleaning procedure implemented on the employed membrane at the end of each ultrafiltration experiment: the system was rinsing with 200 ml of distilled water without recirculation, then 250 ml of cleaning solution, that is 0,5 mM NaOCl in 0,5 M NaOH, recirculate during 30-40 minutes with a rate of 50-100 mL/min, followed by the recirculation of distilled water for 5-10 minutes and ending with a rising with 500 ml of distilled water; for every step, the solution need to be discarded. Thanks to this cleaning procedure, the membrane could be reused more times. It's important to carry out all of the ultrafiltration experiment under rigorous cleaning and strict protocols, in order to assess correctly the mass balance and obtain accurate and reproducible results. Ultrafiltration was carried out using concentration factor (ratio of the initial volume respect to the retentate volume) from 1,07 to 1,73, with the aim to investigate if a permeation model, already proved for higher concentration factor, could be applied for lower values too.

Fig. 13 – AC-1 during the standard filtration (on the left) and during the ultrafiltration experiment (on the right) with a Masterflex L/S system with a Vivaflow 200 PES

2.2.2 Molecular weight cut-off and retention characteristics

The molecular weight cut-off (MWCO) defines the equivalent spherical size of macromolecules that can be retained by a specific membrane and it is usually expressed in kDa or atomic (molar) mass unit (amu). The nominal MWCO is estimated as the rejection rate of ~90% for specific globular molecules (fig. 14) and define the rated pore size for ultrafiltration membrane.

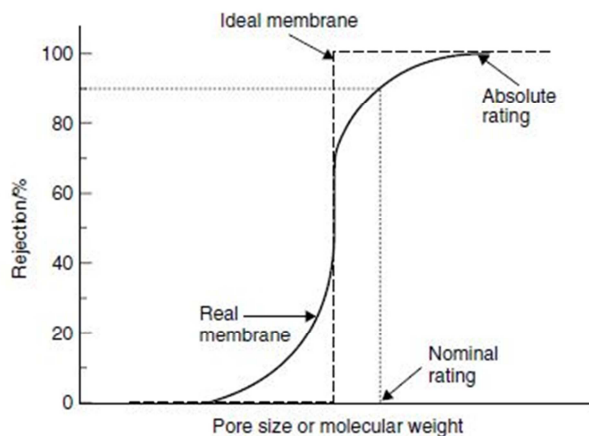

Fig. 14 - Membrane pore size distribution and ratings of ideal and real membranes. From Guo e Santschi (2007).

The experiments were carried out using 50, 10, 5 and 3 kDa PES membranes. The result of each ultrafiltration experiment is the partitioning of molecules of different size between a retentate solution and a permeate solution. Chemical species that have molecular size lesser than the MWCO pass through the membrane, while the concentration of the compounds rejected by the membrane will increase in the remaining solution over time. Thus the permeate solution will be free of particles between 0,2 μm and the MWCO of the membrane used, meanwhile components larger than the pore size are rejected at the membrane surface determining a constant enrichment in their concentration in the bulk solution. Studies on the retention characteristics of ultrafiltration membranes show that, as we can see in fig. 14, a certain percentage of compounds smaller than the rated cut-off can be retained by the membrane, and a varying fraction of higher molecular weight macromolecules can pass through the membrane, depending on the concentration factor and the bulk concentration (Guo & Santschi, 1996). These observations are likely related to electrostatic attraction and repulsion, the slow breakthrough of a small percentage of HMW molecules, steric effects and other physicochemical interactions between the species in solution and the membrane (Buessler et al., 1996).

2.2.3 Ultrafiltration permeation model

The typical application of CFUF technique provides the concentration method, where the pre-filtered sample is concentrated from a single sample reservoir, so the concentration factor (CF) can be obtained from:

$$CF = (\text{Initial sample volume}) / (\text{Retentate volume})$$

Recently, to interpret size fractionation data properly, the permeation and retention behaviour of chemical species have been investigated (e.g. Guo & Santschi, 1996; Dai et al., 1998; Guo et al., 2000; Guo et al., 2001). Since compounds with larger size than the MWCO of a selected ultrafiltration membrane are quantitatively retained and the those having lower molecular weight pass through without retention, a relation between the concentration of a specific element in the permeate (C_p) and the CF can be explained by the following permeation model:

$$\ln C_p = \ln(P_c \times C_f^0) + (1-P_c) \times \ln(CF)$$

where P_c is the permeation coefficient, defined as the ratio of C_p to C_f (concentration in the feed solution) at any given point of the ultrafiltration and C_f^0 is the initial concentration of permeable species in the upstream feed solution. The model works assuming negligible sorption and constant retention characteristics of the membrane, other than a constant partitioning across the membrane for high and low MW solutes. When the element behaves with a constant permeation, a linear relationship between $\ln C_p$ and $\ln CF$ can be found. The slope of the derived equation $(1-P_c)$ gives the P_c value, which is related to the rejection coefficient R_c by $P_c = 1 - R_c$, and could be equal to 1 when there is no retention for that element, resulting in the same concentration of that element in both permeate solution and feed solution at any time of the ultrafiltration. If instead $P_c < 1$, that means that retention occurs at each ultrafiltration cycle, with the consequence that the concentration of any chemical species in the permeate will increase with increasing CF (Guo & Santschi, 1996). The membrane theory (Johnson & Wangersky, 1985) describes how the interaction between particles and membrane works: any particle or molecule with a gyration radius R_p lesser than membrane pore size R_m , can pass through the membrane at a permeation rate proportional to $(R_m - R_p)^2 / R_m^2$. R_p is always >0 , so for the LMW the ratio $(R_m - R_p)^2 / R_m^2$ will be always $<100\%$, with the result that macromolecules P_c values will always result <1 . This means that all of macromolecules will be retained to a certain extent (Guo & Santschi, 2007) according to the $R_c = 1 - C_p / C_f$, that is defined as the fractional reduction in the feed concentration C_f through the membrane. As the P_c value can be calculated from the slope $(1-P_c)$ derived from a linear relationship between $\ln C_p$ and $\ln CF$, the estimation of initial feed concentration (C_f^0) is allowed due to a combination of the values of the intercept ($\ln(P_c \times C_f^0)$) and the slope. Using the estimated C_f^0 , the initial colloidal fraction can be predicted as $1 - C_f^0 / C_T^0$ where C_T^0 is the measured total dissolved concentration.

2.3 Concentration of U and Th

The concentration of the investigated elements in the solution were find out by ICP-MS analysis, using an internal method that requires a calibration fitting the values of an internal standard with different known concentration versus distinct measured concentrations of the investigated elements. The report of the analysis Ref. 3471341328210616 is illustrated in the annex 1.

2.4 Radionuclide activities determination

2.4.1 Preparation of samples

The procedures for preparation of water samples for determination of radionuclide activities by ICP-MS were devised by Michael E. Ketterer, professor at Metropolitan State University of Denver, and can be applied on mine drainage samples, like the Río Tinto ones or similar, either filtered or un-filtered. The first procedural step is the lab-fabrication of the Eichrom Tech. TRU (*TRansUranic*) resin columns, whose purpose is the extraction chromatography. Columns were packed using 3 ml transfer pipets, cutting the top of their bulb and inserting into them small glass wool, in a way that the wool won't be neither too tightly (the flow through the column will be very slow) nor too loose (the resin will leak through). Then the columns were cleaned rinsing with several full volume of warm 2 M HNO₃, allowing it to drain each time. 30±2 mg of TRU resin, whose was mixed with distilled water and then added by pipetting this slurry, were transferred into each column, ensuring that the resin is completely wet and uniformly packed on the top of the glass wool. After ultrafiltration, 10 ml of each sample were pipetted in a pre-cleaned 125 ml polyethylene cups and then acidified with 1 ml of HNO₃ 69% (16 moles/liter). 150 µg of ²²⁹Th were accurately added to each sample. The spike is a solution containing a known concentration of a particular element, whose isotopic composition has been changed by the enrichment of one of its isotopes. The sample to be analysed contains an unknown concentration of the element whose isotopic composition is known, so, when a known amount of spike is mixed with a known weight of a sample, the isotopic composition of the solution can be used to calculate the amount of the element in the sample. This is the base of the isotope dilution analysis, that leads to the determination of the isotopic composition of an element in a sample. In this case a 2×10^{11} atoms ²²⁹Th spike and a 5×10^{11} atoms ²³³U spike were used. After adding the ²²⁹Th-²³³U spike, the samples were heated at 75°C for 2-3 hours to ensure complete equilibration of the mixture (fig. 15). The following step was the sample loading on the columns: the acidified sample solution was extremely carefully poured through the appropriate column, in order that the TRU resin could act and remove saline matrix and pre-concentrates Th and U. Subsequently the extraction of Th and U was performed using appropriate acid: when all the water sample passed through the TRU resin column, each column was rinsed three times with 1 ml of 2 M HNO₃, allowing the complete drainage of each rinse and discarding them. Then Th was eluted by passing six times 1 ml of 1 M HCl and collecting all of them. The Th fractions were completely evaporated by placing the uncapped tubes in a convection oven held at 85-90° C until evaporation was complete. After the completely removal of 1 M HCl, 300 µL of 2 M HNO₃ and 2,7 mL of distilled water were added to each tube; the tubes were capped and heated at 85-90°C for 1 hour to re-dissolved Th. Before U extraction, each column was rinsed again three times with 1 mL of 2 M HNO₃ that were discarded, in order to clean the columns. The U fraction was obtained by collecting in sequence 1 mL of distilled water, 1 mL of 0,05 M ammonium oxalate, and 1 mL of distilled water. In order to gain a controlled and more accurate analyse, replicate samples and standard materials were included, as well as blanks prepared with distilled water and acidified. The standard used was a preparation containing marine coral, which has a known ²³⁴U/²³⁸U equal to $1,148 \pm 0,002$.

2.5 ICP-MS analyses

Inductively Coupled Plasma Mass Spectrometry is the best technique to investigate the isotopic composition of elements. It has several advantages, including a very high sensitivity and a superior detection capability, as well as the high temperature of ICP-MS source that minimize matrix interferences. A mass spectrometer separate charged atoms and molecules on the basis of their mass using a magnetic field. it consists in three essential part, all of them maintained at high vacuum: the plasma source that converts the atoms into ions, the magnetic sector mass analyser and the ion collector. The source is an ICP torch, wherein argon gas flows in its concentric channels (fig. 16). A radio-frequency is generated to supply energy to the load coil, leading to an oscillating electric and magnetic field in the torch. This oscillating field will capture the ions generated by the reaction that takes place when the argon gas is sparked: electrons are separated from the argon atoms and the ions formed collide with other argon atoms, forming the plasma. The sample is introduced through a small orifice in the nebulizer that reduces the solution into an aerosol, which is brought into the torch. Here the aerosol is fragmented due to the high gas pressure and the atoms will ionized toward the end of plasma, travelling together with it. Plasma is an optimal source because of its temperature of 6000-10000°K , but it doesn't allow determinations of negative ions because its typically positively ions composition. To get a stable signal, it's important that the amount of the sample joining the plasma is constant, so an injector system (e.g. a cyclonic chamber, an ultrasonic injector) is needed. Other fundamental component is the peristaltic pump, to ensure the sample will be pushed in the system with extreme stability. Since all the elements of the sample are converted into ions, they are accelerated and reach the mass spectrometer as a narrow ion beam, entering the magnetic field whose field lines result perpendicular to the direction of travel of the ions. Now the ions are deflected by the magnetic field into a curved path of radius r , according to following equation:

$$\frac{m}{z} = \frac{B^2 r^2}{2U}$$

where m/z is the ionic mass/charge ratio, B is the magnetic flux density, U the acceleration voltage (several kV) through which ions pass. So, the heavier ions are deflected less than the lightest ones. The resulting separated ion beams move onwards and the magnetic sector analyser focuses ions of the selected mass on the collector slit. Here, in the collector assembly, they can be detected and processed in a signal: it needs to be amplified to be measured by a digital or analogic voltmeter, that records the numbers of ions arriving at the collector during a given interval. The measurement is passed to the computer for isotope ratio calculations and other analytical outputs. To analyse several isotopes of an element, either the magnetic field or the accelerating voltage can be varied, in a way that the separated ion beams reach the collector successively. The mass spectrum of the element resulting from processing is a series of peaks and valley that represents a distinct mass/charge ratio that identifies each isotope in the mass spectrum, with the height of the peaks proportional to the isotopes relative abundance.

Th and U isotopes were measured with a Thermo Scientific XSERIES 2 quadrupole ICP-MS equipped with a CETAC 5000 ultrasonic nebulizer (fig. 16). The system was tuned and

calibrated by the technician, then was cleaned with milli-q water and a cleaning solution of HNO₃ 2%. The acquisition parameters were for U 100 ms dwell time, 50 sweeps in 25 seconds and a timing washout between 10 and 220 seconds, for Th 20 ms dwell time, 200 sweeps in 17 seconds and a timing washout of 10-300 seconds. Three sequential integrations of each sample was acquired. In order to monitor the sensibility of the analyses, a tune 0,2 ppb for U and the cleaning solution of HNO₃ 2% were random tested together with the samples. A tune for Th was not available, so the analysis were monitored just using the cleaning solution HNO₃ 2%. The instrumentation exhibited a very stable mass discrimination behaviour.

2.5.1 Mass bias factor

This is the process of mass discrimination, that occurs because the ion transport efficiency is not the same for all masses. Light masses or heavy masses will be transported with greater efficiency, in reality. So, instead the measure of the effective value, for example a ratio value of 1,000, the instrumentation gives a slightly different results, such as 1,015 or 0,985. The mass bias factor can be calculated to correct the raw results. For U and Th it is not functional to measure an internal ratio, but it is practical measure $^{238}\text{U}/^{235}\text{U}$ in a sample of naturally occurring U source, like a marine coral. The measured ratio needs to be corrected for the blank values and then it is compared to the true $^{238}\text{U}/^{235}\text{U}$ ratio, that is constant in nature (137,88). The effect of MBF is cumulative and it is necessary to use exponent to adjust the formulae for the difference between the involved isotopes.

2.5.2 $^{234}\text{U}/^{238}\text{U}$ activity ratio

With the spectrometer, the activity of the isotopes is measured. But in terms of ratio between them, a problem will arise because of the $^{234}\text{U}/^{238}\text{U}$ atom ratio will be very small (0,00005472 at secular equilibrium). To get through this problem, it is possible to measure the much larger $^{234}\text{U}/^{235}\text{U}$ ratio, and then cross-multiply. This works because $^{235}\text{U}/^{238}\text{U}$ in nature is constant (1/137,88). To calculate $^{234}\text{U}/^{238}\text{U}$ AR, ^{234}U and ^{235}U measurements, to which the blank signal is subtracted, are needed. Their ratio is then corrected for the MBF and the result is divided for 0,0075448, that is $(^{234}\text{U}/^{238}\text{U})_{\text{nature}} * (^{238}\text{U}/^{235}\text{U})_{\text{nature}} = (0,00005472) * (137,88)$, obtaining the value of $^{234}\text{U}/^{238}\text{U}$ AR.

2.5.3 ^{230}Th activity with ^{229}Th tracer

The signals at masses of the isotopes ^{230}Th and ^{229}Th are needed. After blank-subtract to ^{230}Th signal, the ratio $^{230}\text{Th}/^{229}\text{Th}$ is calculated and then corrected using the MBF. The subsequent step is the calculation of the number of ^{230}Th atoms, multiplying the $^{230}\text{Th}/^{229}\text{Th}$ corrected for the amount of ^{229}Th atoms in the spike. Finally the number of ^{230}Th atoms is converted to mass of ^{230}Th and in activity of ^{230}Th using the specific activity of ^{230}Th ($7,624 \times 10^8$ Bq/g). The concentration of ^{229}Th is determined using the known activity of the solution, the mass of the spike solution added and the specific activity of ^{229}Th ($7,868 \times 10^9$ Bq/g). An example of ^{230}Th calculation is shown below:

- Amount of ^{229}Th spike added = $(0,15 \text{ g solution}) \cdot (200 \text{ mBq } ^{229}\text{Th} / \text{g solution}) = 0,03 \text{ Bq } ^{229}\text{Th}$
- Mass $^{229}\text{Th} = (0,03 \text{ Bq } ^{229}\text{Th}) \cdot 1 \text{ g } ^{229}\text{Th} / 7,868 \times 10^9 \text{ Bq } ^{229}\text{Th} = 3,813 \times 10^{-12} \text{ g } ^{229}\text{Th}$
- Atoms $^{229}\text{Th} = 3,813 \times 10^{-12} \text{ g } ^{229}\text{Th} \cdot (1 \text{ mole} / 229,03 \text{ } ^{229}\text{Th}) \cdot (6,022 \times 10^{23} \text{ atoms} / 1 \text{ mole}) = 1,0026 \times 10^{10} \text{ atoms } ^{229}\text{Th}$

sample 44:

- $(^{230}\text{Th}/^{229}\text{Th})_{\text{measured}} = (43,8 - 0,6125) / 1933,806 \text{ atoms } ^{230}\text{Th} = 0,022332902$
- $(^{230}\text{Th}/^{229}\text{Th})_{\text{corrected}} = 0,022332902 \cdot \text{MBF} = 0,022332902 \cdot 1,0017 = 0,022370955 \text{ atoms } ^{230}\text{Th} / \text{atoms } ^{229}\text{Th}$
- Atoms $^{230}\text{Th} = (0,022370955 \text{ atoms } ^{230}\text{Th} / \text{atoms } ^{229}\text{Th}) \cdot (1,0026 \times 10^{10} \text{ atoms } ^{229}\text{Th}) = 224279616,7 \text{ atoms } ^{230}\text{Th}$
- Mass $^{230}\text{Th} = (224279616,7 \text{ atoms } ^{230}\text{Th}) \cdot (1 \text{ mole} / 6,022 \times 10^{23} \text{ atoms}) \cdot (230,03 \text{ g} / 1 \text{ mole}) = 8,56709 \times 10^{-14} \text{ g } ^{230}\text{Th}$
- Activity of $^{230}\text{Th} = (8,56709 \times 10^{-14} \text{ g } ^{230}\text{Th}) \cdot (7,624 \times 10^8 \text{ Bq } ^{230}\text{Th} / 1 \text{ g } ^{230}\text{Th}) = 6,53155 \times 10^{-05} \text{ Bq } ^{230}\text{Th}$

2.5.4 ^{234}U activity with ^{233}U tracer.

This calculation could not be performed, due to a likelihood contamination occurred during the critical preparation of the samples for the radionuclide determination that led to its determination failure.

Fig. 15 – Preparing samples for radionuclide determination is a critical procedure and requires several steps. In A the samples are heating in order to equilibrate the mixture after adding the ^{229}Th - ^{233}U spike. TRU columns shown in B were used to extract Th (image C) and U. Th fractions were completely evaporated, it can be seen the residue into the uncapped tube (D). Image E shows the collection of U fraction, ready for the ICP-MS analysis .

Fig. 16 - Thermo Scientific XSERIES 2 quadrupole ICP-MS (a) equipped with a CETAC 5000 ultrasonic nebulizer (d). The plasma source (b) is an ideal source, it can reach temperature of 6000-10000°K. c: the ICP torch, wherein argon gas flows in its concentric channels.

3 - RESULTS AND DISCUSSION

3.1 On-site measurements

The measured on-field parameters are listed below in table 3:

Table 3 - Collected samples and respective parameters measured on field using a calibrated multiparametric probe.

| Sample | pH | Redox potential (mV) | Conductivity ($\mu\text{S}/\text{cm}$) | Temperature ($^{\circ}\text{C}$) |
|--------|------|----------------------|--|------------------------------------|
| AC-1 | 2,88 | 469 | 4480 | 26,0 |
| AC-2 | 1,63 | 640 | 22900 | 27,6 |
| AC-3 | 2,16 | 538 | 12370 | 22,4 |
| AC-4 | 5,39 | 71,7 | 2140 | 19,5 |
| AC-5 | 2,35 | 502 | 7270 | 24,5 |
| AC-6 | 5,65 | 163,2 | 175,1 | 16,1 |

As it can be seen, the highest redox potential, equal to 640 mV, and the highest conductivity, that is 22900 $\mu\text{S}/\text{cm}$, correspond to sample AC-2 with pH equal to 1,63, the lowest one. This sample was collected from the waste pile of Peña de Hierro mine. Its water is the more acidic one just because it results from the weathering of a big rock-pile storage of prevailing pyritic waste, whose oxidation leads to the release of a high amount of acidity (H^+), sulphate (SO_4^{2-}), iron and other related trace metals. As expected when AC-4 and AC-6 was sampled, their pH is the highest one due to the water flows from the opposite side of the mountain, where a possible longer way of this little river or a more carbonatic composition of the drained rocks let the water be more alkaline. Within this condition, vegetation and life forms as frogs may develop therein. Where this alkaline water join the main river, precipitation of Fe-oxyhydroxides and secondary sulphates takes place due to the pH rises. The characterization and the quantification of the colloidal particles formed right here could be an interesting subject of further investigation.

3.2 Filtration and ultrafiltration experiments

Filtration was carried out to free the water from the coarser particles and get the first qualitative information about the water with highest particles-content. AC-1 had the more slowly progression in the 0,2 μm filtration process, so it could be considered the sample with the highest content in particles larger than 0,2 μm . Used filters with retained particles were stored for further investigation on particles characterization. At present, it could be presumed that this colloidal material $> 0,2 \mu\text{m}$ consists in inorganic compounds, possibly mainly Fe-oxyhydroxydes, as could be expected in acid mine drainage rivers. Ultrafiltration experiments were carried out on AC-1 using membranes of different MWCO and obtaining a permeate and a retentate solution from each selected concentration factor of each experiments (table 4). Samples were prepared in order to obtain low concentration factors (CFs). They were calculated taking into account that 15 ml of volume of solution would remain into the ultrafiltration tubing system. During the first ultrafiltration experiment, where a 50 kDa membrane was employed, slightly different CFs result because of the shorter intake tubing system, which didn't allow the complete aspiration of the solution

from the reservoir and the consequent collection of sufficient amount of permeate volume needed to the radionuclide determination by ICP-MS analyses. Just for this experiment, in the course of which it was not possible to change the intake tubing system, larger initial volume of solution was placed into the reservoir and consequent larger volume of permeate solution was collected, resulting in CF a little different from the ones obtained from the followed ultrafiltration experiments. Ultrafiltration is a time-consuming procedure, so a longer intake tube replaced the shorter one before starting the 10 kDa ultrafiltration experiment, since the adequate permeate volume to prepare the samples for the radionuclide determination is 20 ml and the collection of this amount is shorter, especially when membranes with lower MWCO are involved. For the fact that 15 ml of solution were retained from the ultrafiltration tubing system, it was not possible to collect the retentate solution for the highest CF, because the difference between the initial volume and the permeate volume of the solution was exactly 15 ml.

Table 4 - List of samples obtained from ultrafiltration experiment developed on AC-1 sample. MWCO is the molecular weight cut-off of the membranes used in the experiments, expressed in kDa; V_i and V_p are the initial volume and the permeate volume of the solution, respectively, and the concentration factor CF is calculated as V_i/V_r , with the volume of retentate solution $V_r = V_i - V_p$. P and R mean permeate and retentate solution. Due to technical difficulties, the volumes involved in the 50 kDa ultrafiltration experiment are slightly distinct from the others and it was not possible to collect the retentate solution for the highest CF (explanation in the text).

| MWCO (kDa) | V_i (ml) | V_p (ml) | CF | P sample number | R sample number |
|------------|------------|------------|------|-----------------|-----------------|
| 50 | 315 | 20 | 1,07 | 1 | 7 |
| 50 | 115 | 20 | 1,21 | 2 | 8 |
| 50 | 95 | 20 | 1,27 | 3 | 9 |
| 50 | 135 | 40 | 1,42 | 4 | 10 |
| 50 | 95 | 40 | 1,73 | 5 | 11 |
| 50 | 55 | 40 | 3,67 | 6 | - |
| 10 | 315 | 20 | 1,07 | 12 | 18 |
| 10 | 115 | 20 | 1,21 | 13 | 19 |
| 10 | 95 | 20 | 1,27 | 14 | 20 |
| 10 | 75 | 20 | 1,36 | 15 | 21 |
| 10 | 55 | 20 | 1,57 | 16 | 22 |
| 10 | 35 | 20 | 2,33 | 17 | - |
| 5 | 315 | 20 | 1,07 | 23 | 29 |
| 5 | 115 | 20 | 1,21 | 24 | 30 |
| 5 | 95 | 20 | 1,27 | 25 | 31 |
| 5 | 75 | 20 | 1,36 | 26 | 32 |
| 5 | 55 | 20 | 1,57 | 27 | 33 |
| 5 | 35 | 20 | 2,33 | 28 | - |
| 3 | 315 | 20 | 1,07 | 34 | 40 |
| 3 | 115 | 20 | 1,21 | 35 | 41 |
| 3 | 95 | 20 | 1,27 | 36 | 42 |
| 3 | 75 | 20 | 1,36 | 37 | 43 |
| 3 | 55 | 20 | 1,57 | 38 | 44 |
| 3 | 35 | 20 | 2,33 | 39 | - |

3.3 Permeation behaviour

As provided by the permeation model, if there is a constant permeation, log of concentration of U and Th in the permeate solution plotted versus log CF should result in a linear relationship described in the equation:

$$\ln C_p = \ln(P_c \times C_f^0) + (1-P_c) \times \ln(CF)$$

where P_c is the permeation coefficient of LMW of the investigated element. On the basis of this model, it can be possible calculate its value from the slope ($1-P_c$) and estimate the amount of the retention for that chemical species at each ultrafiltration cycle. Furthermore, C_f^0 can be derived from the combination of the intercept(b) and the P_c value, using $\exp(b)/P_c$, while the concentration of colloidal fraction of the element is given by calculating the difference between C_f^0 and the initial measured dissolved concentration (C_t^0) of the chemical specie under discussion (Guo & Santschi, 1996; Guo et al., 2000).

3.3.1 U discussion

The application of the permeation model using U concentration in the permeate samples produces a moderately good explanation of the behaviour of the LMW U interacting with the two membranes, with a coefficient of determination $R^2 = 0,658$ and $R^2 = 0,694$ for the 50 kDa membrane and for the 3 kDa membrane respectively (fig.15). We have few values in the data set, but R^2 could be increased repeating the experiments and operating with more and different CF, so that the regression will seem to fit better the data. The constant permeation coefficients are $P_c = 0,813$ for U ultrafiltered with 50 kDa membrane and $P_c = 0,626$ for U ultrafiltered through 3 kDa membrane. It means that, for each cycle of ultrafiltration, the 50 kDa membrane let 81 % of LMW U pass through it and 19 % will be retained as compounds with a molecular size higher than 50 kDa., while a 63% of U can pass through the 3 kDa membrane which retains 37 % of U. Previous results about U behaviour ultrafiltered at 5 kDa gave a value of $P_c = 0,847$ (Casas-Ruiz & Barbero, 2015), so the permeation behaviour of U resulting from our experiment can be considered the same even at low concentration factors. Although previous works mention artifactual retention of the dissolved species at low concentration factors, due to the retention of LMW molecules in the retentate, that leads to overestimate the colloidal concentration (Guo et al., 2000; Guo et al., 2007), here the value of initial concentration derived from the model is higher than the one measured in the 0,2 μm sample, resulting in a negative value of estimated colloidal fraction. This could suggest a probable contamination or that large artifacts occurred among the membrane and the chemical species. As is illustrated in table 1 section 1.7.2, colloidal U fractions in natural waters result considerably high. However, there is a lack of studies on colloidal U fraction in acidic environment as the Río Tinto one, but previous results show that the permeation model estimates around 9 % of U associated to 5 kDa colloidal fraction (Casas-Ruiz & Barbero, 2015).

3.3.2 Th discussion

Thorium reveals an opposite trend for the 50 kDa membrane ultrafiltration, showing a decrease in concentration of Th in the permeate solution with increasing the concentration factor (fig. 17). The permeation coefficient resulting from the model amounts to 1,944, but this is not a realistic value because of its effective meaning: P_c is defined as the ratio of C_p (concentration in the permeate) and C_f (feed concentration) and is related to the rejection coefficient R_c by $P_c = 1 - R_c$. P_c is equal to 1 when the concentration in the permeate is the same of the one in the feed solution, meaning that there is no retention for that species (Guo & Santschi, 1996). A value > 1 for the P_c implies a negative value for R_c , that is, the membrane is not giving back truthful information and it is not retaining in quantitative form. With regard to the 3 kDa ultrafiltration experiment, behaviour of thorium can be described by a permeation model with a $P_c = 0,369$, that means the membrane retain 63 % of Th. Casas-Ruiz & Barbero (2015) reported a value of $P_c = 0,812$ for Th ultrafiltered at 5 kDa membrane. This time this disagreement could be explained with the artefactual retention of Th < 3 kDa by the membrane. Again, the permeation model returns a negative estimation of the colloidal fraction due to the value of initial concentration calculated from the model which is higher than the one measured in the 0,2 μm sample.

Casas-Ruiz & Barbero (2015) applied the traditional method on their sample and got a colloidal U fraction of 2,2 % and colloidal Th fraction of 6,3 % which indicates that the 5 kDa membrane does not retain dissolved U and Th as previously evidenced (Guo et al., 2007). The colloidal abundance is calculated from:

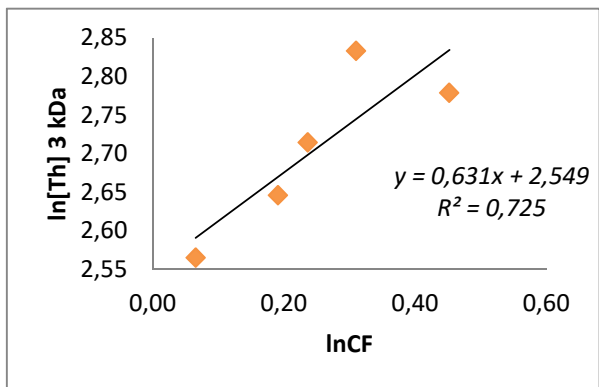

$$[\text{colloidal}] = \frac{[\text{retentate}] - [\text{permeate}]}{CF}$$

obtaining again negative values for both Th and U in the samples underwent to 50 kDa ultrafiltration, but values up to 0,6 % for U and up to 2,1 % for Th in the 3 kDa colloidal fraction. This results could be considered consistent with the previous ones.

Fig. 17 - Permeation models for U and Th with 50 kDa and 3kDa membrane. Explanation in the text. Results about Th 50 kDa could be not considered truthful. P_c is the permeation coefficient, C_f^0 is the initial feed concentration, both derived from the model. C_t^0 is the concentration measured in the pre-ultrafiltration sample.

Table 7 - Samples used for the permeation model with their concentration, calculated colloidal fraction and recovery. Type: p and r mean permeate and retentate solution respectively. CF is the concentration factor obtained from V_0/V_r where V_0 is the initial volume and V_r is the difference between initial volume and permeate volume (V_p). $Diss_f$ is the dissolved fraction, $Coll_f$ is the colloidal fraction, both at each point of ultrafiltration founded calculating the recovery (explanation in the text). C_0 is the measured initial concentration.

3.3.3 U and Th concentration

In general, both the investigated elements show no significant differences among the distinct samples obtained from the different experiments and the pre-ultrafiltration sample (filtered to 0,2 µm). The range of U concentration is 4,73 – 6,54 µg/L, extended among the solutions resulting from the 3 kD ultrafiltration experiments. The lowest value belongs to the permeate sample of 3 kDa membrane ultrafiltered with a CF=1,07, while the highest one is associated to the retentate solution after 3 kDa ultrafiltration experiment with CF=1,57. Th concentration covers a little more extended range, that is 13,0 – 28,0 µg/L. Another time the lowest value is given by the permeate sample from 3 kDa membrane with the lowest CF, but the highest one is detected in the solution permeated through the 50 kDa membrane. Uranium in seawater amounts to 3,3 ppb (e.g. Ku et al., 1977), while in common surface waters it presents temporal and spatial variability strongly dependent on the local redox conditions (Plater et al., 1992), but still predominantly in the order of ng/L (see table 1,

section 1.7.2). The extreme elevated value of U concentration results from acidic conditions of the study area, as a consequence of low pH (<3) surface water conditions that lead to the mobilization of high levels of natural radionuclides. Furthermore, the area is characterized by acidic volcanoclastic rocks (into which U is naturally concentrated), that under AMD suffer the continue dissolution of minerals and the subsequent release of the associated elements into the waters. Data on dissolved Th concentration in natural waters are lacking, but Langmuir & Herman (1980) reported previous measured values of dissolved thorium in surface waters, showing values of 0,001-1 ppb in fresh surface waters, which cover a pH range between 5 and 8, and a value of 0,00064 ppb in surface seawater, that have pH around 8. Th uses to be present not in dissolved form in natural water, but it should be noted that the samples show a Th concentration one order of magnitude higher than U, that on the contrary is commonly founded as dissolved form. This can be explained by the acidic environment of Río Tinto area that leads to the dissolution of solid phases, colloids included, and provides the conditions in which Th can exist in solution as Th^{4+} and in high concentrations. It can be supposed that such high concentrations of dissolved form of both the elements could emerge from the elevated zeta potential values of the particles $> 0,2 \mu\text{m}$, isolated by the classical filtration and expected to be amorphous oxy-hydroxides of iron and aluminium, with the consequence that the high charged ions will be rejected from the particles surfaces and could concentrate in the solution. Our results are consistent with previous data from Río Tinto data, that exhibits very high concentrations at pH below 2,5, as expected from the theoretical behaviour of these elements under low pH and oxidizing conditions, reaching values up to 200 $\mu\text{g/L}$ for U and up to 600 $\mu\text{g/L}$ for Th (fig.18).

Fig. 18 - U and Th concentrations versus pH in Rio Tinto waters. From Casas-Ruiz & Barbero (2015).

3.3.4 Mass balance

A classic method to calculate colloidal fraction considers the measurements of all the fraction involved in each ultrafiltration experiment, and allows an accurate mass balance that is critical, even not very sensitive, to assess the recovery of the operations (Guo & Santschi, 1996). The mass balance is obtained using the following equation:

$$\text{Recovery (\%)} = \frac{(C_p \times V_p) + (C_r \times V_r)}{C_0 \times V_0} \times 100$$

where C_p , C_r and C_0 are the measured concentration in the permeate, retentate and initial solution respectively, and V_p , V_r and V_0 are the respective volumes involved in the ultrafiltration experiments. A recovery > 100 % indicates a contamination, while a recovery < 100 % means a loss of the element during the ultrafiltration process. Applying this method on the samples, dissolved and colloidal fractions for the ultrafiltration at each CF can be appreciated and are listed in table 7. It can be observed that U recovery results reasonably good. In contrast, the recovery of Th (mainly < 80%) reveals large losses of this element during ultrafiltration experiments. It might be due to the nature of Th, whose dissolved form as Th^{4+} is highly charged and physicochemical interactions with the ultrafiltration membranes, which, in general, are negatively charged, can be developed, with the consequent retention of Th. It seems that low CF for Th are inadequate to extract it and reach a permeate that will be representative of its actual permeation behaviour. This observation could explain the failure of the application of the permeation model for Th to the samples deriving from 50 kDa ultrafiltration experiments, which cannot describe quantitatively the ultrafiltration behaviour of Th in this so acidic waters.

3.4 ICP-MS results

3.4.1 $^{234}\text{U}/^{238}\text{U}$ activity ratio

The budget let us perform the ICP-MS analysis just on half of the ultrafiltered samples, so the samples deriving from the larger MWCO ultrafiltration experiment (50 kDa) and the ones from the lowest MWCO ultrafiltration experiment (3 kDa) were selected to carry out the analysis on them. Within these 22 samples, the 0,2 μm filtered sample (representing the initial solution whose concentration is investigated), 8 blanks, 6 coral solutions, 3 coral solutions diluted x 100, other than 2 replicates of the samples and a tune 0,2 ppb solution for U were submitted to the ICP-MS analysis, in order to carry out a monitored and more accurate analyse. Three measurements for each samples was acquired, with their mean, standard deviation and the RSD calculated by the computer. Then, in order to calculate the $^{234}\text{U}/^{238}\text{U}$ activity ratio, necessary corrections for each measurement were individually performed, and the mean, the standard deviation and the RSD of the final result can be calculated. The complete list of the analysed samples and the entire results of the analysis, with their corresponding corrections, are exposed in the annex 2 and 3 respectively.

The accuracy and precision of the instruments were verified by the analysis on the marine coral samples, which have a known value of $^{234}\text{U}/^{238}\text{U}$ activity ratio (AR) equal to $1,148 \pm 0,002$. The resulting calculated $^{234}\text{U}/^{238}\text{U}$ AR on the coral sample are about 1,15% less than the known value. This little difference is consistent with the typical bias of spectroscopy methods of investigation, that usually amounts as high as 2%. Calculated $^{234}\text{U}/^{238}\text{U}$ activity ratios are in a range with a minimum amounting at 1,761 and a maximum value of 2,060. The minimum value is given by a replicate of a sample whose measurement shows a $^{234}\text{U}/^{238}\text{U}$ activity ratio of 1,957. This deviation probably arises from an inaccuracy during the samples preparation process, because of the difficulties during their handling and their processing. Excluding this result, no significant variations can be seen in the activity ratio of

$^{234}\text{U}/^{238}\text{U}$ irrespectively of this is calculated neither for different pore size of the membrane nor in the retentate or in the permeate. Results are listed in table 5. Previous works in Río Tinto waters registered a $^{234}\text{U}/^{238}\text{U}$ AR ranging between 1,5 to 3 (Ketterer et al., 2011), explained as a consequence of weathering processes as well as the ones related to acid drainage, but it should be close to unity when the complete dissolution of the solid matrix occurs. Such a conclusion was found out by Barbero et al. (2014), with their leaching experiments on solid samples of the area that reveals their $^{234}\text{U}/^{238}\text{U}$ AR close to one, consistent to the secular equilibrium reached between ^{234}U and ^{238}U isotopes in the bulk material. Another acid mine drainage case that could be compared with Río Tinto one is the Ogoya Mine one in Japan, where Tedori and Kakehashi Rivers waters show a $^{234}\text{U}/^{238}\text{U}$ AR around 3,1 (Yamamoto et al., 2010). Here the authors attribute the exceptional high $^{234}\text{U}/^{238}\text{U}$ AR values (up to $16,8 \pm 1,8$), founded in samples closest to the mine zone, to the deeper underground water having high ^{234}U concentration due to preferential leaching of ^{234}U under the neutral and reducing conditions. Samples investigated in this work report a $^{234}\text{U}/^{238}\text{U}$ AR average of $2,002 \pm 0,007$ that is consistent with further results concerning dissolved matter from Río Tinto water and amounting to $2,01 \pm 0,08$ exposed by Hierro et al. (2013). The disequilibrium is imputable to the excess of ^{234}U related both to the recoil effect, enhanced by the weathering that leads to a reduction in the grain size, and the acidic water preferentially lixiviates ^{234}U respect to ^{238}U from minerals in the mining areas.

Table 5 - Calculated $^{234}\text{U}/^{238}\text{U}$ activity ratios. MWCO is the molecular weight cut-off of the membranes used, p and r mean permeate and retentate respectively, CF is the concentration factor.

3.4.2 ^{234}U activity

It was not possible carry out this information due to a likelihood contamination occurred during the handling and the processing of the samples for the radionuclide determination that led to the failure in its calculation.

3.4.3 ^{230}Th activity

The activity of ^{230}Th varies little in a range between 0,056 mBq/L and 0,169 mBq/L, with an average of 0,144 mBq/L. The lowest value belongs to the 50 kDa permeate sample resulting from the lowest CF, while the highest value is given by the sample 8, retentate obtained from the 50 kDa ultrafiltration experiment with a CF of 1,27. The typical ^{230}Th concentration in natural waters is one or more orders of magnitude lower than our results (see table 2, section 1.6.3). With the exception of the sample 44, it can be detected that the general trend is slightly lower ^{230}Th activity values in permeate samples and a bit higher values in the retentate ones. One might suppose this observation could be related to the typical behaviour of Th in the most of natural conditions i.e. in natural waters Th is mostly an insoluble elements and has affinity with solid phases, resulting in higher concentration in the retained fraction. But this is not the case of Río Tinto area, where pH is lower than 3 and even the most insoluble phases could not exist in solid form. Thorium can be present in solution as Th^{4+} only in very acidic waters (Rai & Serne, 1978). Thus, the acidic environment promotes the desorption of thorium from particles and colloids, while mineral phases undergo dissolution. Both these occurrences could be considered as further contributions of ^{230}Th into the solution, whose existence in solution is mainly related to the decay of ^{234}U (Osmond & Ivanovich, 1992), isotope that, as we discussed, determines its enrichment in the water due to the α -recoil and its subsequent easier leaching. In fact, the $^{230}\text{Th}/^{234}\text{U}$ ratio is almost exactly the same (0,127-0,146) testifying their direct correlation.

Table 6 - Calculated ^{230}Th activity. MWCO is the molecular weight cut-off of the membranes used, p and r mean permeate and retentate respectively, CF is the concentration factor. The determination of $^{230}\text{Th}/^{234}\text{U}$ ratio was useful to understand if ^{230}Th into the solution exists because mainly related to the decay of ^{234}U (explanation in the text).

4 - SUMMARY AND CONCLUSIONS

The acid mine drainage environment of Río Tinto area presents the ideal conditions to evaluate the role of colloidal phase in the transport and the fate of trace elements like U and Th in aquatic system. The behaviour of these elements in natural waters is well known, but Río Tinto waters have a pH <3, there is no carbonate that can act as ligands for both investigated elements or neutralize the acidity of the water, and colloids are expected in very high concentrations into the water, due to their formation related to the increasing of pH occurring when clear water from precipitation or of no-contaminated tributary join Río Tinto waters.

Natural river waters underwent firstly to traditional filtration at 0,2 μm , process that, with its slowness, qualitatively reveals a high content in particles > 0,2 μm . Then, filtration at 0,45 μm proceeded, followed by ultrafiltration experiments for different membrane pore size and distinct concentration factors. Low increasing concentration factors were used to investigate if a permeation model is applicable even for low value.

U behaviour can be described by a permeation model that provides a permeation coefficient (P_c) of 0,813 for U < 50 kDa and $P_c = 0,626$ for U < 3 kDa. For both the ultrafiltration experiments, the value of initial concentration derived from the model is higher than the one measured in the 0,2 μm sample, resulting in a negative value of estimated colloidal fraction. This could suggest a probable contamination or that large artifacts occurred among the membrane and the chemical species. Using the traditional method to estimate U associated to the colloidal fraction for both the membrane pore sizes, again negative values for U in the samples underwent to 50 kDa ultrafiltration can be calculated, but values up to 0,6 % for U associated to 3 kDa colloidal fraction, that means the 3 kDa membrane does not retain dissolved U. Thus, the permeation model can just show that little retention for U occurs and that the permeation behaviour of U can be considered the same even at low concentration factors. But using low concentration factors, the colloidal concentration cannot be estimated by the permeation model.

The application of the permeation model on Th 50 kDa samples failed because the membrane was not retaining in quantitative form, but it could be possible derived a $P_c = 0,360$ for Th from the 3 kDa experiments. This low value could result from artefactual retention of Th <3 kDa by the membrane. A 6,3% of colloidal Th fraction is calculated from the traditional method, such a low value meaning the membrane doesn't retain dissolved Th.

Compared to the content of U and Th in common natural water (order of ng/L for U and far less for Th), concentrations of both elements are at least three orders higher, but with no appreciable differences among the concentrations in the permeate and the retentate solutions. The high values of the measurements were expected because of the nature of acid mine drainage condition: U derive from the dissolution of aluminosilicates by the leaching of the acidic volcanic lithologies present in the area, Th can stay as dissolved form in extreme acidic conditions, and colloids and all of solid phases, with which Th has high affinity, will be disintegrated.

It can be argued that the colloidal fraction $>0,2 \mu\text{m}$ consist in amorphous oxy-hydroxides of iron and aluminium that, in acid mine drainage environment, get elevated zeta potential values and will not uptake the high charged U(VI) and Th(IV), rejecting them from the particles surfaces and leading to such high concentrations of dissolved form for both the elements. It is important carry out the characterization of the colloidal material for each size membrane experiment, in order to validate this scenario and understand how colloids composition affects the processes of elements uptake from the solution.

Recovery for U is excellent, while the membranes determined large losses of Th during each ultrafiltration experiments (recovery $<80\%$). This could be due to interactions between the negatively charged membrane and the highly charged Th dissolved form. It seems that low CF for Th are inadequate to extract it and reach a permeate that will be representative of its actual permeation behaviour.

Using a standard material to assess more accuracy in the ICP-MS analysis, we found a 1,15% of uncertainty that can be accepted because of the spectroscopy methods can have up to 2 % of bias. $^{234}\text{U}/^{238}\text{U}$ activity ratios range between 1,761 and 2,060. The disequilibrium among the ^{234}U and ^{238}U isotopes is attributable to the excess of ^{234}U related both to the recoil effect, and the acidic water preferentially lixiviates ^{234}U respect to ^{238}U from minerals in the mining areas.

The handling and the processing of the samples is a critical point to achieve a good success in all of the work, but difficulties and contamination occurred and led to problems in interpretation of some results and no less to failures in get some information, like the ^{234}U activity. On the other hand, we obtained a range between 0,056 mBq/L and 0,169 mBq/L for ^{230}Th activity, whose presence in solution is mainly related to the decay of ^{234}U . Again the acidic environment promotes the desorption of Th from particles and colloids, while mineral phases undergo dissolution. Both these occurrences could be considered as further contributions of ^{230}Th into the solution.

It would be interesting to investigate the behaviour of the other elements characterizing the AMD system, in order to better understand the relationships between them and U and Th associated, relations that can suggest and confirm these radionuclides derive from leaching of the host rock. Together with the characterization of the colloidal form, this will be the aim of the next project that the research team of the University of Cádiz will advance during the next months, and in which I will participate to carry on the investigation and improve the data on Río Tinto area.

ACKNOWLEDGMENT

I'd like to thank all of the people who supported me in the choice that got me where I am. My family: even just without one of them I wouldn't be able to achieve this objective. I really love each of them: my father, my mother, my brother, my two sisters and each respective partners. I realised how much they are important to me.

My Italian friends in Bologna: I am really grateful to their endurance with my impossible behaviour and bad mood during my always stressful time. Bianca, partner in a multitude of projects, I shared with her all of this university years, five years of studies, choices, sacrifices, angers, tears, joyful times, adventures and significant experiences together. Matteo and Carlotta, I don't know how they can still stand me, living with me was very hard. Thank you for staying close to me. Franz, his friendship and his support was essential for me, for both my university career and my personal life. Stiv, without his help I couldn't understand a lot of things. Sergio, Deiv, Greta, Pierfra, Richi, Marco, Matteo A., Sara M., Siria, Sara V., Andre, Lu, Cri, Gio F., Gio M., Chiara, Miriana, Gabri L. and all of the others classmates that I shared the passion for geology with. I thank my friends I cannot mention every people met during my academic years, because they are so much, but I would like to say that professors, researchers, students and the staff of geology department, all of them have been like a family for me and I am fond of them. I want to remember Bruno Capaccioni, he left me a lot of teachings and good memories, I miss him.

I want to thank Enrico Dinelli, who promoted the participation in the Erasmus program and for being my supervisor.

Many thanks to my Spanish supervisor Luis Carlos Barbero González, who taught me everything about the work, how to face several coming out situations and their related problems. He had the patience to put up with me and my questions and doubts. I appreciated the support and the assistance from Melquiades Casas Ruiz, I thank him so much. I thank Antonio Benítez Rodríguez (Beni), who explained, showed and helped me in all of the ICP-MS operations. Special thanks to Micheal E. Ketterer, professor at Metropolitan State University of Denver, for his suggestions and comments coming from his great experiences about analytical, instrumental and radiochemistry.

I cannot forgot the support from my friends all along Chiara, Sara and Vale.

Last but not the least, I would like to thank all of the international people met thanks to the Erasmus program in Cádiz, each of them was lovely and surprising, cheering me every time that I needed. Especially all of the flatmates passed by Sagasta 22, I will never forget anybody. Among them, I need to mention Serena and Barbara, they have been so close to me in the worst and dispiriting moments, encouraging me despite everything.

Thanks to everybody.

INFORME DE ANÁLISIS Ref: 3471341328210616.

Puerto Real, 4 de Julio de 2016

Análisis de 23 muestras líquidas suministradas por D. Luis Carlos Barbero González (Departamento de Ciencias de la Tierra de la UCA). El suministrador identifica las muestras como aguas ácidas filtradas, proporcionándolas en recipientes de plástico.

- **FECHA DE RECEPCIÓN:** 21/06/16.
- **ANÁLISIS REQUERIDO:** Elementos: U y Th.
- **ANALISTA:** Antonio Benítez Rodríguez. Técnico División de Espectroscopia (AAS-ICP).
- **INSTRUMENTAL:** : Espectrómetro ICP-MS serie X2 de Thermo Elemental.
- **TRATAMIENTO PREVIO REALIZADO A LA MUESTRA:** Dilución por duplicado de dos muestras y el resto una réplica.

Los resultados son los siguientes:

| Muestra | [Th] µg/L | [U] µg/L | Muestra | [Th] µg/L | [U] µg/L |
|---------|------------|-------------|---------|------------|-------------|
| 0 (a) | 21,1 ± 1,0 | 5,40 ± 0,23 | 34 | 13,0 ± 0,6 | 4,73 ± 0,30 |
| 0 (b) | 19,2 ± 0,2 | 5,20 ± 0,10 | 35 | 14,1 ± 0,6 | 5,20 ± 0,10 |
| 1 | 28,0 ± 0,2 | 4,91 ± 0,11 | 36 | 15,1 ± 0,6 | 5,42 ± 0,30 |
| 2 | 19,7 ± 1,3 | 5,22 ± 0,30 | 37 | 17,0 ± 0,5 | 5,10 ± 0,03 |
| 3 | 17,5 ± 0,5 | 5,40 ± 0,10 | 38 | 16,1 ± 0,3 | 5,60 ± 0,11 |
| 4 | 17,1 ± 0,7 | 5,36 ± 0,12 | 39 | 14,2 ± 0,6 | 5,21 ± 0,13 |
| 5 | 16,7 ± 1,2 | 5,44 ± 0,40 | 40 (a) | 13,5 ± 0,6 | 5,10 ± 0,10 |
| 6 | 15,6 ± 0,8 | 5,23 ± 0,10 | 40 (b) | 13,7 ± 0,7 | 5,20 ± 0,20 |
| 7 | 14,2 ± 0,6 | 4,81 ± 0,20 | 41 | 14,6 ± 0,6 | 5,41 ± 0,20 |
| 8 | 16,0 ± 1,2 | 5,41 ± 0,30 | 42 | 14,0 ± 0,5 | 5,13 ± 0,20 |
| 9 | 15,0 ± 0,5 | 5,30 ± 0,10 | 43 | 15,0 ± 0,2 | 5,30 ± 0,10 |
| 10 | 15,2 ± 0,4 | 5,31 ± 0,12 | 44 | 19,4 ± 0,5 | 6,54 ± 0,11 |
| 11 | 15,7 ± 1,4 | 5,30 ± 0,30 | | | |

Resultado expresado como el valor medio de tres medidas instrumentales ± desviación estándar.
